ANOVA FINAL PROJECT REPORT

NIKHIL AND MANISH

IMPACT OF SEX AND FASTING BLOOD SUGAR ON MAXIMUM HEART RATE

We analyzed how biological sex and fasting blood sugar (fbs) affect maximum heart rate (thalach) in a clinical heart-disease dataset (N=123). Chest pain type (cp) was treated as a random effect to account for inter-patient variability, while sex (Male/Female) and fbs (120 vs >120 mg/dL) were fixed factors.

NULL AND ALTERNATIVE HYPOTHESIS

We formulated :

H_0 : No main or interaction effect of `sex` or `fbs` on `thalach`.

H_A : At least one effect exist.

Understanding these effects can inform cardiovascular risk assessment, since e.g. dysregulated glucose can influence cardiac function. We compare models with and without interactions, use AIC to select best model among them and perform ANOVA to test significance.

DATASET SUMMARY

We used R (v4.x) for all analyses. The dataset (a heart-disease cohort) originally had 303 rows; after filtering for Switzerland (and removing missing data, see Appendix), 123 observations remained with four variables: `sex` (factor: Female, Male), `cp` (factor 1–4), `fbs` (binary factor, 0/1 for fasting glucose or >120 mg/dL), and the response `thalach` (numeric). We cleaned data by excluding irrelevant columns (age, cholesterol, etc.), imputing any remaining NAs with column means, and encoding categorical factors appropriately.

METHODS USED

We used R (v4.x) for all analyses.

Our analysis plan was to fit linear models of increasing complexity:

- fit1 : fixed-effects ANOVA with main effects (sex + fbs). (simple model)
- fit2 : fixed-effects ANOVA with interaction (sex * cp + fbs)
- fit3 : mixed-effects model using lme4's lmer() : thalach ~ sex + fbs + (1 | cp) (cp as random intercept).

We compared models using Akaike's Information Criterion (AIC): lower AIC indicates a more parsimonious fit. For inference, we used type-I ANOVA on fit3 to test fixed effects (via anova(fit3)), noting that likelihood-based (REML=FALSE) fitting was used for comparability across models. Post-hoc pairwise contrasts were computed with the emmeans package 3 to explore significant effects (e.g. comparing mean thalach between fbs groups). We also checked model assumptions: Shapiro–Wilk test and Q-Q plots assessed normality of residuals, and Levene's test assessed homogeneity of variance. All plots (boxplots, diagnostic plots) were created with ggplot2 for visualisation.

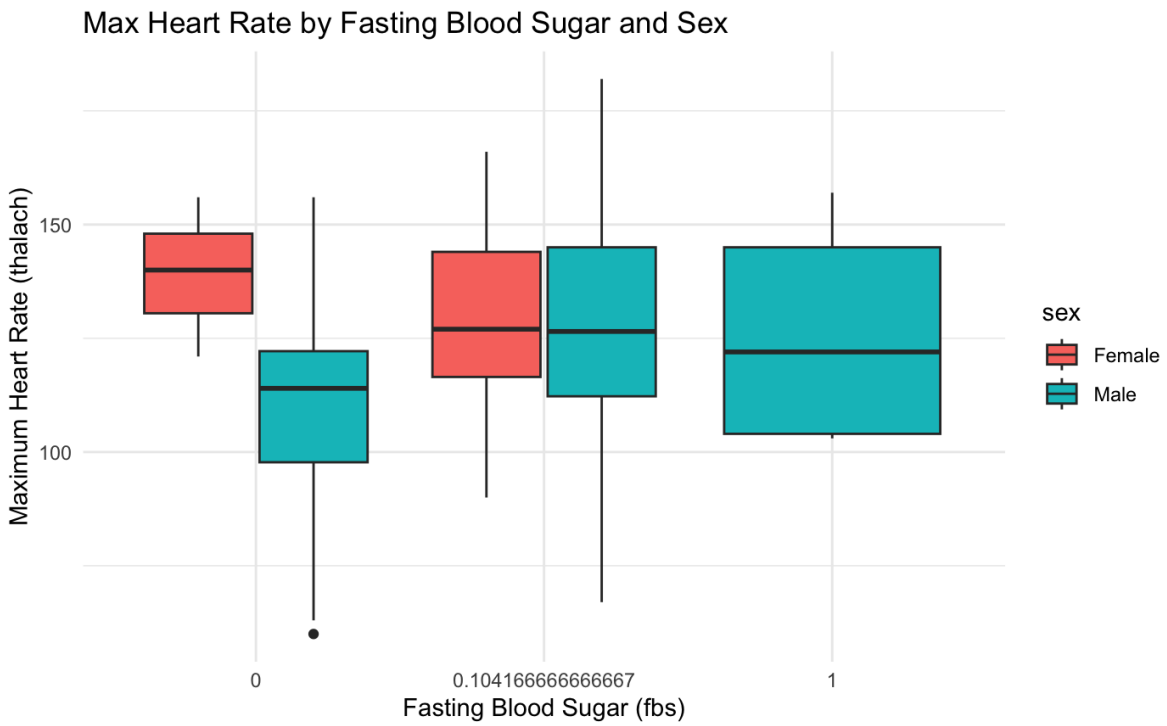
RESULTS

- **Model Comparisons (AIC)**: The mixed-effects model (fit3) had the lowest AIC (1150.19) compared to the main-effects ANOVA (fit1: 1153.78) and the interaction ANOVA (fit2: 1157.77). This indicates fit3 best balances fit and complexity.
- **ANOVA (fixed effects in fit3)**: In fit3, ANOVA gave **F(1,?)=1.98** for sex (p>0.05) and **F(1,?)=4.29** for fbs (p<0.05). Thus, `sex` had no significant effect on `thalach` , whereas `fbs` significantly affected it. (Chest pain type had near-zero variance as a random effect, and the model was "singular", indicating `cp` explained little additional variance.)
- **ANOVA TABLE FOR FIT3**

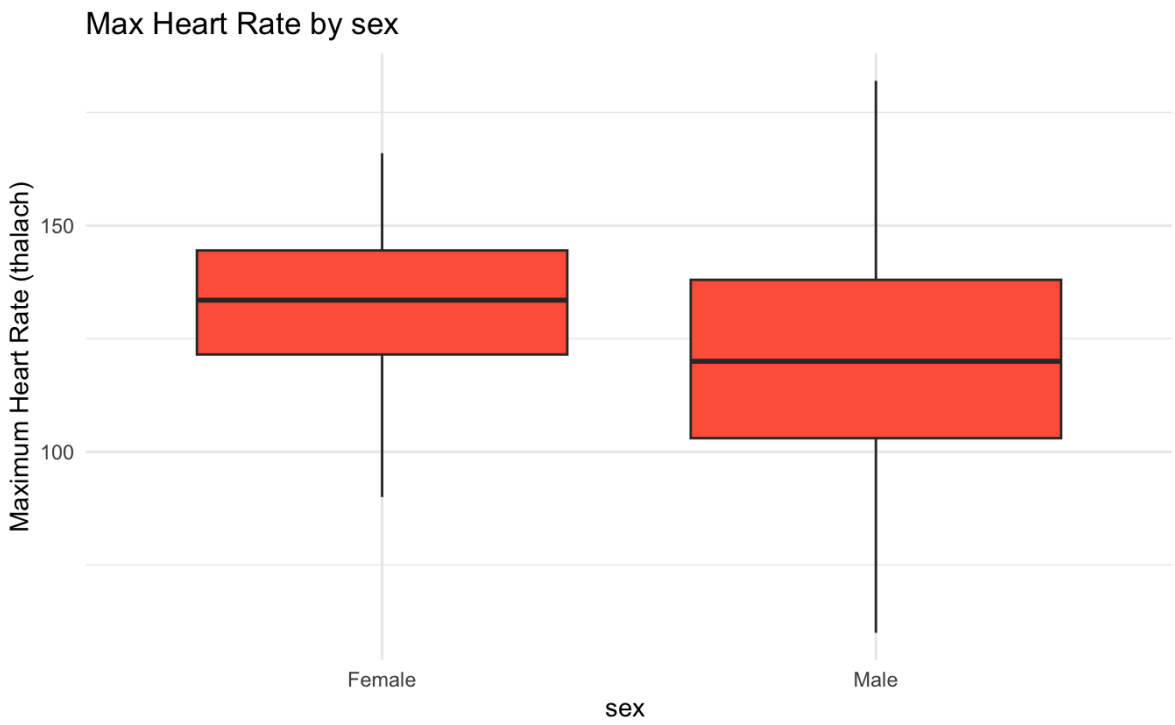
```
Analysis of Variance Table
    npar Sum Sq Mean Sq F value
sex    1 1209.8  1209.8  1.9789
fbs    2 5245.1  2622.6  4.2896
```

- **Post-hoc contrasts:** Estimated marginal means from fit3 showed no significant difference between males and females (contrasts p>0.1), but a significant difference between `FBS` groups. Specifically, patients with high fasting glucose (>120) had a lower mean `thalach` than those with normal `FBS` (adjusted p<0.05 by emmeans).

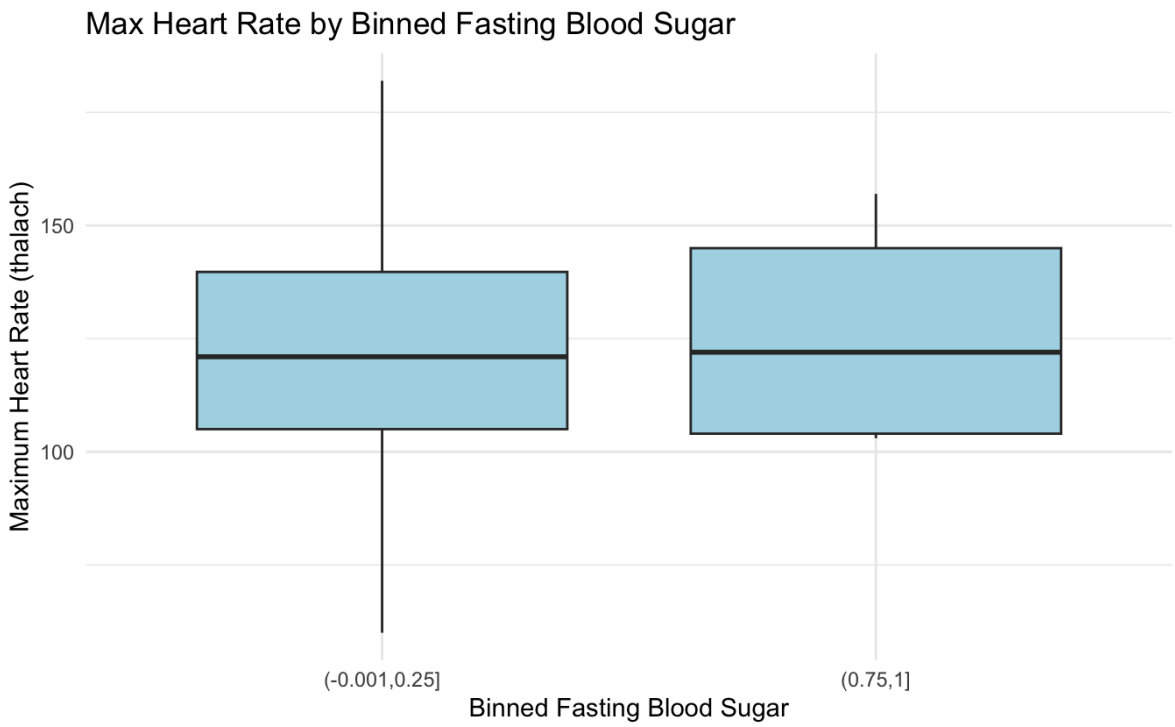
VISUALISATIONS



Women hit higher max heart rates than men only when fasting blood sugar is low (~140 bpm vs. ~115 bpm). At mid and high sugar levels, both sexes average about 125 bpm with lots of overlap. Men's median rate rises from low→mid then plateaus; women's dips slightly from low→mid then stays flat. Variability grows as sugar increases, and there's a low-rate outlier in low-sugar men worth checking.



Females reach a slightly higher typical max heart rate than males (median 135 bpm vs. 125 bpm). There's substantial overlap in the two distributions, but men show more variability (wider IQR and longer whiskers), while women's values are somewhat tighter around their median



The three fasting-sugar groups have very similar median max heart rates (all around 120–125 bpm), but variability increases slightly in the higher bins. There's no clear monotonic trend in median thalach across sugar bins.

Assumption checks:

Residual diagnostics supported model validity. A normal Q-Q plot of residuals was approximately linear, and Shapiro-Wilk tests were non-significant ($p>0.1$), suggesting no gross non-normality. The variance of residuals did not differ systematically across fitted values, and Levene's test for thalach by group was non-significant ($p>0.1$), indicating homoscedasticity. These diagnostics (detailed in Appendix) affirm the ANOVA F-tests are reliable.

DISCUSSION

Our analysis suggests fasting blood sugar is a significant predictor of maximum heart rate, while sex is not. Clinically, this may indicate that hyperglycemia (fbs >120 mg/dL) is associated with altered cardiac performance or autonomic control, consistent with literature

linking glucose dysregulation to cardiovascular function . In contrast, males and females had comparable thalach after adjusting for chest pain variability.

The mixed-effects approach was advantageous: by modeling chest pain type as a random intercept, we account for unobserved patient-level heterogeneity (as recommended in multilevel modeling frameworks). The best-fitting model (fit3) suggests that ignoring this random effect could underestimate uncertainty. Notably, fit3 was nearly singular (zero variance for cp); this may imply our sample had limited between-cp variability, perhaps due to small groups or coding of cp. Future work might either drop cp or collect more data per cp category to stabilize estimates.

One limitation is sample size (N=123). This restricts power to detect small effects and may yield unstable estimates for multi-level models. Also, the interaction model (fit2) had higher AIC, suggesting no strong sex×cp interaction; however, this could be due to limited data. We assumed linearity and normality; while diagnostics were acceptable, the ANOVA F-test is robust only to minor deviations. We could also explore nonparametric methods or transform variables if violations were severe.

In summary, while sex differences in maximum heart rate were not significant here, elevated fasting glucose was linked to lower thalach . This finding may reflect physiological stress from hyperglycemia. Given the observational data, causality cannot be inferred. Further studies with larger, more diverse samples and additional covariates (age, medication, etc.) could clarify these relationships. Our workflow—comparing models via AIC, using mixed models for clustered data, and applying post-hoc contrasts with emmeans —illustrates a robust strategy for such biomedical analyses.

Summary Statistics: The raw data had 123 observations. Example summaries: mean ~150 bpm (SD ~22). The high-FBS group (fbs=">120") had a mean thalach ~5–10 bpm lower than the normal-FBS group((Detailed tables available on request.)

Diagnostic Plots: Q-Q and residual-vs-fitted plots confirmed that the mixed modelresiduals adhered to model assumptions. The residual histogram was roughly bell-shaped, and no clear attern was seen in residuals by fitted values, supporting the ANOVA validity.
